**Dirac Strings and the Nonperturbative
Photon Propagator in Compact QED**

ABSTRACT: In the Villain approximation of $D = 2 + 1$ compact QED, the monopole part of the partition function factorizes from the Dirac string part, which generates the photon propagator. Numerical experiments in exact compact QED confirm this result: photon mass pole M_γ , originally nonzero, is insensitive to monopole prohibition but almost vanishes if Dirac strings are prohibited.

hep-lat/9212002 3 Dec 92

I. Motivation

Lattice calculations [1, 2] have evaluated the mass poles $M_{g,q,\gamma,e}$ of gluon, quark, photon, and electron propagators in LGT(lattice gauge theory). More recently, “photon” propagators in abelian-projected $SU(2)$ LGT were studied [3]. Remarkably the $SU(2)$ photon mass, as in cQED₃₊₁(compact QED in 3+1 dimensions) [2], is nonzero in the confine phase and vanishes in the deconfine phase. Since computing these masses, which are gauge variant [4], requires gaugefixing to either Landau or maximal abelian gauges it is unclear whether they are indicators of real physics, lattice regularization artifacts, gaugefixing artifacts [5], or some combination thereof.

The abelian-projection potentially provides a concrete framework for investigating the relationship between LGT gluon masses and confinement via abelian-projected photon masses [6]. This possibility beckons us to clarify the relationship between nonperturbative photon masses and confinement in cQED. To this end, this Letter focuses on cQED₂₊₁, a QCD-like model with local gauge invariance, chiral symmetry breaking, and area-law electron confinement. cQED confines because quantum monopole fluctuations [7] restrict electric flux to Abrikosov tubes of width λ in a dual Meissner effect [8]. Recent LGT simulations resolve a finite London penetration depth λ which, following Landau-Ginzburg theory, can be identified as the inverse mass of an effective gauge potential A_μ^{eff} .

As described below, the nonperturbative zero-momentum photon propagator mass pole M_γ in cQED₂₊₁ is also resolvable and nonzero. The observation of two mass scales, λ and M_γ , raises the following question: How, if at all, is A_μ^{eff} related to primary photon field A_μ and λ to M_γ ? Are they equivalent?

Indeed, as shown below, λ and M_γ in cQED₂₊₁ are not blood relatives. The gauge-invariant quantity λ arises from quantum monopole fluctuations while M_γ arises from gauge-variant Dirac strings.

II. Monopoles, Gaugefixing, and Dirac Strings

Let $\partial_\mu h_x \equiv h_{x+\hat{\mu}} - h_x$, $\partial_\mu^* h_x \equiv h_x - h_{x-\hat{\mu}}$, and $\square \equiv \partial_\mu^* \partial_\mu$. Link and plaquette angles in cQED,

$$\theta_\mu \equiv A_\mu + 2\pi n_\mu, \quad -\pi \leq A_\mu < \pi, \quad n_\mu \in \mathbf{Z} \quad (1)$$

$$F_{\mu\nu}[A] \equiv \partial_\mu A_\nu - \partial_\nu A_\mu, \quad (2)$$

depend only on photon A_μ . The cQED action $S_c \equiv \beta \sum_{\mu < \nu} (1 - \cos F_{\mu\nu})$ is invariant under local gauge transformations

$$\delta\theta_\mu \equiv -\partial_\mu \omega_x, \quad \delta A_\mu \equiv (A_\mu - \partial_\mu \omega_x) \text{Mod}[-\pi, \pi) - A_\mu. \quad (3)$$

While plaquette $\exp(iF_{\mu\nu})$ is gauge-invariant, a gauge transformation inducing unequal shifts of n_μ on the four links of $F_{\mu\nu}$ shifts $F_{\mu\nu}$ by a 2π multiple. $F_{\mu\nu}$ decomposes into a gauge-invariant part $\Theta_{\mu\nu} \in [-\pi, \pi)$ and a gauge-variant integral kink $N_{\mu\nu} \in \mathbf{Z}$ such that

$$F_{\mu\nu} \equiv (\Theta + 2\pi N)_{\mu\nu}, \quad (4)$$

$$\delta F_{\mu\nu} = 2\pi \delta N_{\mu\nu} = \partial_\mu (\delta\theta - \delta A)_\nu - (\mu \leftrightarrow \nu). \quad (5)$$

Because $\cos F_{\mu\nu} = \cos \Theta_{\mu\nu}$ in S_c , required since $N_{\mu\nu}$ is gauge-variant, $\frac{\beta}{4} F^2$ would be a misleading approximation to S_c . More valid is Villain's periodic gaussian approximation $S_c \rightarrow S_c^V$ where

$$e^{-S_c^V} \equiv \sum_{\{N\}} e^{-\frac{\beta}{4} \sum_x (F[A] - 2\pi N)^2}, \quad (6)$$

Figure 1A. Monopoles(●) and Dirac strings(—) on a typical periodic 5^3 lattice before gaugefixing.

$\sum_{\{N\}} \equiv \prod_{\mu,\nu} \sum_{N_{\mu\nu}=-\infty}^{\infty} \delta(-N_{\nu\mu}, N_{\mu\nu})$, and $F^2 \equiv \sum_{\mu,\nu} F_{\mu\nu}^2$. The sum over $\{N\}$ in (6) is necessary to maintain gauge invariance under (5). Within an $N_{\mu\nu}$ potential well the Maxwell equation is $\partial_\mu^* F_{\mu\nu} = K_\nu \equiv 2\pi \partial_\mu^* N_{\mu\nu}$. Conserved current K_μ acts as a virtual source of electromagnetic charge. Quantum $N_{\mu\nu}$ fluctuations can lead, via the Maxwell equation, to a nonzero effective M_γ if

$$\langle \mathcal{O}_\mu K_\mu \rangle_N = M_\gamma^2 \langle \mathcal{O}_\mu A_\mu \rangle_N + \dots \quad (7)$$

In (7) $\langle \rangle_N$ refers to the Boltzmann average over $N_{\mu\nu}$ and operator $\mathcal{O}_\mu$ serves to absorb $D = 2 + 1$ rotational invariance.

While $N_{\mu\nu}$ is gauge variant, spatial combinations of them form gauge-invariant structures which influence $\Theta_{\mu\nu}$ as follows. According to the Hodge-DeRham theorem

$$\Theta_{\mu\nu} = \epsilon_{\mu\nu\alpha} \partial_\alpha^* \phi + \partial_\mu \alpha_\nu - \partial_\nu \alpha_\mu, \quad (8)$$

$$N_{\mu\nu} = \epsilon_{\mu\nu\alpha} \partial_\alpha^* m + \partial_\mu l_\nu - \partial_\nu l_\mu \quad (9)$$

where $\phi, \alpha_\mu \in (-\infty, \infty)$ and $m, l_\mu \in \mathbf{Z}$. ϕ and m are invariant under (3), α_μ transforms like θ_μ , and l_μ like $(A - \alpha)_\mu / 2\pi$. $\Theta_{\mu\nu}$ (and similarly $N_{\mu\nu}$) has 3 independent polarizations while ϕ and α_μ are 4 functions because $\Theta_{\mu\nu}$ is invariant under $\delta\alpha_\mu = -\partial_\mu \omega_x$. In vector notation Eq. (4) becomes $\vec{B} = \vec{H} + 2\pi\vec{\eta}$ where the total $\vec{B}$, physical $\vec{H}$, and Dirac string $\vec{\eta}$ magnetic (actually electromagnetic) fields are

$$\vec{B} \equiv \nabla \times \vec{A}, \quad \vec{H} \equiv \nabla \phi + \nabla \times \vec{\alpha}, \quad \vec{\eta} = \nabla m + \nabla \times \vec{l}. \quad (10)$$

It will be advantageous to recast $\vec{\eta}$ in terms of its divergence and curl

$$q \equiv \nabla \cdot \vec{\eta} = \square m, \quad \vec{\rho} \equiv \nabla \times \vec{\eta} = \nabla(\nabla \cdot \vec{l}) - \square \vec{l}. \quad (11)$$

Since $\nabla \cdot \vec{B} = 0$ by (10), $\nabla \cdot \vec{H} = -2\pi q$, that is, q causes dislocations in the physical field $\vec{H}$. By tautology q is the magnetic monopole density, gauge

Figure 1*B*. The same lattice after Landau gaugefixing. While monopole positions do not change, there are more Dirac strings.

invariant since m is gauge invariant. $\vec{\rho}$, a continuous current wrapping around $\vec{\eta}$, is gauge-variant.

In general, kinks occur either in monopoles, Dirac strings connecting a monopole antimonopole pair, or Dirac string loops. Loops can either be homologically trivial or toroidally wind around the periodic boundaries. Monopole charge density q is gauge-invariant but the number of string loops and the length and shape of all strings vary with gauge. Figure 1A shows a monopole and Dirac string arrangement in a representative $\beta = 1.0$, periodic 5^3 non-gaugefixed lattice. Figure 1B shows the same lattice after 5000 Landau gaugefixing sweeps. There are typically more Dirac strings after Landau gaugefixing than before, as depicted.

III. Factorization of Photon Propagator from Monopoles

Upon adopting the condition $\nabla \cdot \vec{l} = 0$ and ignoring Laplacian zero modes, Eqs. (4)-(11) constitute 1-to-1 variables changes $\{N\} \rightarrow \{m, \vec{l}\} \rightarrow \{q, \vec{\rho}\} \rightarrow \{\phi, \vec{\alpha}\}$ where, if $\square \Delta_{x,y} = -\delta_{x,y}$, $\partial_\mu^* \Delta^{\mu\nu} = 0$, and $\square \Delta_{x,y}^{\mu\nu} = -\delta_{\mu,\nu} \delta_{x,y}$, then $\phi = 2\pi \sum_y \Delta_{x,y} q_y$ and $\alpha_\mu = A_\mu - 2\pi \sum_y \Delta_{x,y}^{\mu\nu} \rho_{\nu y}$. Following (4), (6), and (8)

$$Z_c^V \equiv \int_A e^{-S_c^V} = Z_m[0] \times Z_{Al}[0], \quad (12)$$

$$Z_m[\xi] \equiv \sum_{\{q\}} e^{\sum_x \xi_x q_x - 2\pi^2 \beta \sum_{x,y} q_x \Delta(x-y) q_y}, \quad (13)$$

$$Z_{Al}[0] = \int_\alpha e^{-\frac{\beta}{4} \sum_x F^2[\alpha]}, \quad \alpha_\mu \in (-\infty, \infty). \quad (14)$$

Eq. (12) relies on the quadratic character of the Villain approximation and $\sum_x \epsilon_{\mu\nu\lambda} F_{\mu\nu} \partial_\lambda^* \phi = 0$; $\mathcal{O}(\Theta^4)$ corrections from the $\cos \Theta$ s of S_c would ruin factorization. (14) says $\vec{\alpha}$ is a massless noncompact vector particle.

The dilute gas expansion and occupation number resummation over $q \in \{0, \pm 1\}$ of Z_m in (13) yields [7]

$$Z_m[\xi] \propto \int_{\Phi} e^{-\frac{1}{4\pi^2\beta} \sum_x (\nabla(\Phi-\xi))^2 - 2\lambda^{-2} \cos \Phi} \quad (15)$$

where $\lambda^2 = 2\pi^2\beta e^{-2\pi^2\beta\Delta(0)}$. Scalar Φ is semiclassically identified with ϕ in (8) because, since $\sum_x \xi_x q_x = \frac{1}{2\pi} \sum_x \partial_\mu \xi_x \partial_\mu^* \phi_x$, comparing (13) to (15) yields

$$\frac{1}{2\pi} \langle \partial_\mu \phi \rangle_m = \frac{1}{Z_m} \frac{\delta Z_m}{\delta \partial_\mu^* \xi} \Big|_{\xi \rightarrow 0} = \frac{1}{2\pi^2\beta} \langle \partial_\mu \Phi \rangle_{\Phi}. \quad (16)$$

Following (10) this identification yields

$$\langle \nabla \cdot \vec{H} \rangle_{Alm} = -2\pi \langle q \rangle_m = 0, \quad (17)$$

$$\langle \vec{H}_y \vec{H}_x \rangle_{Alm} = \langle (\nabla \times \vec{\alpha})_y (\nabla \times \vec{\alpha})_x \rangle_{Al} + \frac{4\pi^2}{Z_m} \frac{\delta^2 Z_m}{\delta \nabla_{\xi_y} \delta \nabla_{\xi_x}}. \quad (18)$$

If $\beta/\lambda \ll 1$, (17) and (18) are reproduced by an $M_\gamma = \lambda^{-1}$ *free* photon $\vec{A}^{\text{eff}}$ with $\vec{H}^{\text{eff}} \equiv \nabla \times \vec{A}^{\text{eff}}$, that is, $\nabla \cdot \vec{H}^{\text{eff}} = 0$ and $\langle \vec{H}_y^{\text{eff}} \vec{H}_x^{\text{eff}} \rangle_{\text{eff}} \approx \langle \vec{H}_y \vec{H}_x \rangle_{Alm}$. The latter relation relies on the masslessness of $\vec{\alpha}$ in (18), a consequence of (14), and $\cos \Phi \rightarrow -\Phi^2/2$ in (15). $\vec{A}^{\text{eff}}$ is the massive Landau-Ginzburg photon and λ the London penetration depth.

The $\vec{A}$ propagator is generated by $Z_{Al}[J]$, defined by adding $J \cdot A$ to the action in (6), which does not affect factorization (12). Thus the $\vec{A}$ mass M_γ has nothing to do with monopoles q and, hence, M_γ is not directly related to λ . A remaining logical possibility, which we do not exclude, is that λ and M_γ are coincidentally related via the statistical mechanics of monopoles and $\vec{\rho}$ loop gasses. $\vec{A}$, unlike $\vec{\alpha}$, may be massive because $J \cdot A$ breaks the pure $\vec{\alpha}$ -dependent form of $Z_{Al}[0]$. Manipulations like those leading to (13) yield

$$Z_{Al}[J] = \int_A \sum_{\{\vec{\rho}\}} e^{\sum_x (J + \pi\beta\rho) \cdot A - \frac{\beta}{4} F^2 - \pi^2\beta \sum_y \rho \cdot \Delta \cdot \rho}.$$

Figure 2. (A)cQED with action S_c ;
 (B)cQED with monopoles forbidden;
 (C)cQED with kinks forbidden;
 (D)quadratic approximation $S_c \rightarrow S_E$, kink-creating gauge transformations allowed;
 (E)quadratic approximation $S_c \rightarrow S_E$, kink-creating gauge transformations forbidden.

Z_{Al} is the partition function of a Coulombic $\vec{\rho}$ loop gas, “loop” since $\nabla \cdot \vec{\rho} = 0$. Interestingly $\vec{\rho}$ is a mixed state in the gas since for M_γ to be nonzero $\sum_{y,y'} \Delta_{x,y}^{\mu\alpha} \Delta_{0,y'}^{\nu\beta} \langle \rho_{y,\alpha} \rho_{y',\beta} \rangle_{\vec{\rho}}$ must have a negative norm massless mode to cancel the α pole and an independent M_γ mode. Note that even though photons A_μ are uncharged they suffer confinement since, heuristically, the “adjoint” Wilson loop obeys $\langle \prod_{l \in \text{loop}} A_l \rangle \approx \langle \prod_{l \in \text{loop}} \sin \theta_l \rangle \propto \text{Re} \langle \prod_{l \in \text{loop}} e^{i\theta_l} \rangle$, where cross terms are suppressed by gauge invariance.

IV. Numerical Experiments

We have shown that the A_μ propagator decouples from monopoles in the Villain approximation and, accordingly, M_γ is not a consequence of monopoles. Numerical experiments summarized in Figure 2 support this result in exact cQED₂₊₁. $\beta \times M_\gamma$, a dimensionless number in $D = 2 + 1$, is the log of the ratio of successive $\vec{p} = 0$ photon propagator timeslices. The numerical photon operator and gauge condition are $S_\mu \equiv \sin \theta_\mu$ and $\partial_\alpha^* S_\mu = 0$. The computation is based on 500 configurations on $17^2 \times 19$ lattices. The first configuration—independently for each β value—is thermalized by 500 forty-hit, 40%-acceptance Metropolis sweeps and 5000 checkerboard gaugefixing sweeps. Configurations thereafter are separated by 5 forty-hit Metropolis sweeps and 5000 checkerboard gaugefixing sweeps. Errors are jackknife sigmas based on 10 450-configuration subaverages. Configurations 1–50 are omitted from the first subaverage, 51–100 from the second, and so forth.

“A” in Figure 2 refers to cQED in Landau gauge; “B” to Landau gauge cQED with monopoles prohibited [9]; “C” and “E” to cQED with kinks prohibited. Monopoles prohibition is implemented by starting with the $\theta_\mu = 0$

configuration and linkwise forbidding monopole-creating updates with the insertion of $\prod_{\{x\}} \delta_{q,0}$ into the link measure. Kinks are prohibited either by inserting $\prod_{\{N\}} \delta_{N,0}$ into the link measure("C") or by replacing $\cos F_{\mu\nu}$ in S_c with $S_E \equiv \frac{\beta}{4} F_{\mu\nu}^2$ ("E") where (2) defines $F_{\mu\nu}$.

Landau gaugefixing, which cannot change q , proceeds normally in B. Since maintaining kink prohibition disallows kink-creating gauge transformations which may be necessary to achieve Landau gauge, a good Landau gauge is not achieved in C and E. Nonetheless the photon propagator is easily resolved in all cases and, in agreement with factorization (12), M_γ is relatively insensitive to monopole prohibition but very sensitive to kink prohibition. The small residual M_γ in C is attributable to the $\mathcal{O}(\Theta_{\mu\nu}^4)$ terms in S_c which ruin factorization (12). "D" is also based on the action S_E . Unlike in E, kink-creating gauge transformations are permitted during Landau gaugefixing in D. From the S_E standpoint D, corrupted by action-changing kink creation and annihilation, is gauge *inequivalent* to E. The difference between M_γ in D and E, gauge equivalent from the S_c viewpoint, is an indication of how much kinks generated by the Landau gaugefixing algorithm contribute to M_γ . The smallness of M_γ in D suggests that the kinks responsible for M_γ in A are present in the pre-gaugefixing configurations and not created during Landau gaugefixing.

M_γ and kink-number density ρ , two gauge-variant quantities, are correlated. In cases A-E at $\beta = 1.8$ in Landau gauge, $\rho_A = .41(.01)$, $\rho_C \equiv 0$, $\rho_D = .23(.004)$, and $\rho_E \sim 10^{-5}$. Since the $\beta = 1.8$ monopole number density is $8.0(1.1)10^{-3}$, forbidding monopoles doesn't change the kink density and $\rho_B = \rho_A$. In the same β range the Axial gauge ρ_A is smaller than the Landau gauge ρ_A by $\sim 50\%$ and M_γ smaller by $\sim 70\%$.
